CATTLEYA SPECIES AND THEIR CULTURE
BASED ON AN ARTICLE BY WILLIAM P. ROGERSO
Published in the Orchid Digest, Vo. 68 (4)

The information I share here about Cattleya species and their culture is based mostly on observations accumulated over a 20-year period as a hobbyist grower.

Cattleya species are important to our understanding of the genus and the hybrids. The species are the fundamental building blocks of hybrids, and one of the best ways to understand hybrids is to appreciate the growth habits and characteristics of their species ancestors. Species are interesting because they comprise a wide variety of distinctive and unusual flowers. All sorts of unique shapes, fragrances, textures, and colors have evolved in nature, and it is fascinating to experience them all. Most Cattleya species are very fragrant, with broad ranges of different and unusual fragrances across the genus. Finally, Cattleya species exhibit a variety of distinctive and different growth cycles. Many Cattleya hybrids send out one growth after another whenever there is enough sun. In contrast, most species have quite sharply defined annual growth cycles. These different growth patterns can be intriguing to learn about. Of course, such distinctive growth patterns can be a double-edged sword to the grower. While this makes them intellectually more interesting, growing them well becomes more of a challenge. You can basically water most hybrids without worrying about rest periods, and simply repot them in the spring. Most species however, need distinct rest periods and are quite particular about when they are repotted. You must understand this to grow them successfully.

Bifoliates and Unifoliates

Cattleya species are often divided into two broad subgroups based on the number of leaves on top of each pseudobulb. Unifoliates have a single leaf; those with two (or sometimes three, leaves, depending on the species) are bifoliates. It is useful to further divide unifoliates into two subgroups, which I call “large-flowered unifoliates” and “small-flowered unifoliates.” Withner (1988) lists 48 Cattleya species; of these, 15 are large-flowered unifoliates, 22 are bifoliates, and 9 are small-flowered unifoliates. Today, due to recent taxonomic reclassifications, 42 species will be addressed in this article.

My classification of each species is shown in Table 1.

The large-flowered unifoliate group includes all of the large-flowered, mostly lavender, species that were avidly collected by Europeans in the nineteenth century, and which were used to create the traditional large-flowered unifoliate “corsage” hybrids so popular until the 1970s. Individual flowers on these species tend to be large (from five to more than nine inches across) and plants generally bear three to five flowers per inflorescence. Each bloom tends to display the round, flat form that orchid judges view as desirable. These plants are quite robust and grow well in cultivation (notable exceptions are C. dowiana and C. dowiana var. aurea). Size of the vegetative parts does not vary dramatically among the various species. In general, pseudobulbs and leaves are between one and two feet tall for all these species; pseudobulbs tend to be quite full and stout.

Bifoliates generally have smaller, waxier flowers, and many more blooms per inflorescence. They exhibit a much broader range of colors, and many species have spotted petals and sepals. Flowers of bifoliates are much less likely to show the round, flat form considered ideal in judging. Plants generally have thinner pseudobulbs, and show a much larger range of plant sizes than large-flowered unifoliates. The smallest species, such as C. forbesii, are only around six inches tall, while the largest species, such as C. tigrina (leopoldii) and C. guttata, can grow five to six feet tall. Generally speaking, bifoliates tend to be a little more finicky to
grow than the large-flowered unifoliates. In particular, they seem more resentful of repotting.

Small-flowered unifoliates are probably the least well-known group of cattleyas. While they share with large-flowered unifoliates the trait of having only one leaf per pseudobulb, their flowers are generally more similar to those of the bifoliates, i.e., they are often smaller, with poorer shape, and a larger number of flowers per inflorescence. While some of the members of this group are fairly large plants, comparable in size to the large-flowered unifoliates, many are virtually dwarfs. For example, *C. luteola* and *C. kerrii* are, on average, less than six inches tall. Some of the larger species, such as *C. maxima* and *C. iricolor*, are fairly robust, easy-to-grow plants with cultural requirements comparable to those of large-flowered unifoliates. Some of the smaller species, though, can be more difficult to grow successfully.

**Growth Patterns and Repotting Time**

An essential rule when cultivating *Cattleya* species (or most other sympodial orchids, for that matter) is to “repot only when new roots emerge.” In this article I explain what this means and why it is so important, then review the various growth patterns of cattleyas—in particular, when new root growth occurs. The bloom times or other stages of the annual growth cycle provided here are based on observations of my own plants in a greenhouse in the Chicago area. From conversations with friends living in more southern areas of the U.S., blooming times for many of the species can likely be a few weeks earlier in more southern areas.

The “repot only when new roots emerge” rule follows from two basic facts about cattleyas. First, each lead sends out a single flush of roots once—and only once—in its lifetime. Roots grow down into the medium for the next few months, until they reach maturity and stop. No new roots will emerge from the old lead, and, furthermore, very few, if any, new roots will grow from the existing roots once they have matured. Even when plants do send out new root branches from existing roots, this tends to happen at the same time as new roots emerge from the new pseudobulb. The only way for the plant to grow new roots is to send up another lead, and for new roots to emerge from this new lead.

The “repot only when new roots emerge” rule follows from two basic facts about cattleyas. First, each lead sends out a single flush of roots once—and only once—in its lifetime. Roots grow down into the medium for the next few months, until they reach maturity and stop. No new roots will emerge from the old lead, and, furthermore, very few, if any, new roots will grow from the existing roots once they have matured. Even when plants do send out new root branches from existing roots, this tends to happen at the same time as new roots emerge from the new pseudobulb. The only way for the plant to grow new roots is to send up another lead, and for new roots to emerge from this new lead. Second, the repotting process is generally very hard on roots, resulting in extensive damage even when done carefully. Since roots are tender, and tend to intertwine and cling to pieces of the potting medium and the pot, dislodging roots from the pot and from the decayed potting medium generally causes substantial damage. Since repotting so extensively damages existing roots, it is critical to repot cattleyas only when they are about to send out new roots that can replace the damaged roots.

The ideal time window for repotting is fairly brief. If you repot earlier than a few weeks before new roots emerge, the plant may suffer dehydration stress during the period between repotting and emergence of new roots. However, new root tips are extraordinarily tender, and brushing the emerging tips even very lightly against the side of a new pot is likely to crush them or break them off. It is therefore almost impossible to repot the plant without damaging new roots if they have emerged more than a quarter of an inch from the lead. About a one-week period exists from when the first emerging roots are visible until they have grown too

You can cope with this narrow time window of repotting opportunity in two ways, and I recommend both of them. First, constantly inspect your orchids for signs of new root growth, and be ready to repot them immediately. Second, learn about each plant’s growth pattern, so you can anticipate when to repot. The precise point in the growth cycle at which new roots emerge can vary dramatically among different cattleyas (as I explain below), but any particular plant tends to exhibit the same pattern over and over again. Once you know an orchid’s growth cycle, it is simple either to repot it a few weeks before it will send out roots, or to be vigilant so you can repot it at the first sign of new roots. I generally keep an eye on entire groups of orchids that I know root at the same time; the emergence of new roots on any one of these plants is a signal to repot all of them.

Cattleya species exhibit two sharply distinct patterns of growth. In one growth pattern (which I call “root before bloom”), roots emerge as a new lead grows; blooming occurs only after the lead and roots are mature and basically finished growing. In the other growth pattern (which I call “root after bloom”), a new lead sends out roots only after it has fully matured and bloomed. Cattleyas that follow the “root before bloom” growth pattern often bloom in fall, winter or spring. They typically send out new leads and roots during the spring and summer months so the leads are generally fully mature by the time fall arrives. At this point the orchid enters a rest phase that lasts until the plant’s internal clock tells it to bloom. After blooming, the plant perhaps enters another rest period and begins the cycle anew. Plants in this group sometimes send out successive leads during the summer growing period. The plant stores up all

of these leads and then they all bloom simultaneously during the blooming period. Table 2 and Table 3 list some of the unifoliate and bifoliate species that follow the ‘root before bloom’ growth pattern, and their period of blooming. Most large-flowered unifoliate species follow this growth pattern. Almost all of the fall/winter/spring-blooming unifoliate hybrids descend from these species and follow the same growth pattern.

Cattleyas that follow the “root after bloom” growth pattern often bloom in late spring, summer or fall. An orchid in this group sends up new leads in late winter, spring or summer and blooms almost immediately as the leads reach maturity. Roots emerge immediately after blooming. Many of them, particularly bifoliates, enter a long rest period after rooting. In this group of plants, if a plant sends up successive leads in the same season, each lead will bloom as it matures. Some bifoliate and unifoliate species that follow this growth pattern are listed in Tables 4 and 5. Most bifoliate species and hybrids derived from them follow the “root after bloom” pattern. While orchid growers often associate this growth pattern only with bifoliates, a number of large-flowered unifoliates exhibit this pattern. For example, C. lueddemanniana sends out new leads over the winter months, then blooms in March. Only after blooming do leads send out new roots. It is more typical for unifoliates in this group to send out new leads in spring, which then bloom in summer or early fall. This group includes C. warscewiczii, C. dowiana, and C. rex. Many summer and fall blooming unifoliate hybrids follow this pattern. For example, the very famous yellow hybrid Rhyncholaeliocattleya Toshie Aoki has almost exactly the same growth pattern as C. dowiana var. aurea, which figures prominently in its parentage.

</table>
Orchid growers who aren’t aware of the difference in these two growth patterns tend to repot all of their orchids in the spring or early summer when new leads are emerging. Of course, this is precisely the correct time to repot those in the “root before bloom” group. However, results are much less satisfactory for the “root after bloom” group; these species make their largest and most heroic growth effort of the year in a very short period of time by sending out a new lead that blooms almost immediately. The new lead sends out no new roots during this explosion of growth and instead relies completely on the existing root structure from older leads to sustain itself. Repotting these cattleyas at this time of year effectively destroys many of the plant’s existing roots at just the time it is going to depend most heavily on them. Plants repotted at this time of year often become severely dehydrated and do not recover fully for years. In my view, it is no coincidence that most of the Cattleya species that people view as being difficult to grow belong to the “root after bloom” group. Many people routinely repot these plants at the wrong time in their annual growth cycle.

Some of the species in the “root after bloom” group are not completely reliable in their rooting behavior and occasionally send out new roots either while the new lead is growing or while it is blooming. These plants should be repotted when the new roots emerge, even if they emerge before the plant blooms. Therefore, one needs to be particularly vigilant with this group and check for early root growth.

I list four species in Table 6 that are “oddballs” in the sense they do not follow either of the two growth patterns discussed above. Although *C. aclandiae* and *C. violacea* are very similar in many respects to the “root after bloom” bifoliates, they are perhaps best classified as having their own growth pattern, which I call “root while blooming.” They send up new leads in spring/summer; these bloom almost immediately as they mature, without any rest. However, roots sometimes emerge from new leads while they are still growing or blooming, and only sometimes wait until after leads finish blooming. It is therefore best to repot these two species when a new lead emerges, instead of waiting for it to bloom. Another unusual feature of these two bifoliates is that after their first growth finishes blooming, *C. aclandiae* and *C. violacea* almost always send out a second new growth which blooms a month or two later.

</tbody>
</table>
Many of my plants bloom three times during the summer period. In contrast, most of the ‘root after bloom’ bifoliates bloom only once per season. Only rarely do they send up a second lead that blooms later in the summer. Plants grown in more southern areas than Chicago may be more likely to send up a second growth that also blooms.

*Cattleya walkeriana* and *C. nobilior* have perhaps the most unusual growth pattern of all. They generally send out special leafless growths in winter and early spring that bloom immediately as the leads mature. Roots may or may not emerge from these blooming growths. Then, after the plants have bloomed, regular leaved growths begin to grow in March/April/May that generally do not bloom. Roots tend to emerge from these non-blooming growths as they grow. Therefore, the best time to repot these species is after blooming, when the new leaved growths emerge in March/April/May.

### Other Aspects of Culture

My goal in this section is to highlight particular cultural practices I recommend, rather than to present a complete discussion of all aspects of orchid culture suitable for a beginner. When asked to summarize the key aspects of cattleya culture in a few simple rules, I tell people the following: (a) repot only when new roots are emerging, (b) provide a lot of sunlight, (c) let plants dry out between waterings, and (d) do not over-pot, otherwise the potting medium decays too quickly.

#### Light

One of the most common and serious cultural problems I observe in cattleyas grown in the United States (other than the Southeast and California) is they do not receive enough light. In Chicago, where I grow my orchids, my greenhouse is roofed with acrylic that transmits approximately 85 percent of natural sunlight. It has full southern exposure and I generally use no additional shading even during the summer. My plants have very sturdy light green leaves and generally bloom their little hearts out. Dark green leaves, weak growths, and few or no blooms are signs of too little light. I encourage you to experiment (carefully) with giving your cattleyas more light, and observe any changes this brings about. Keep in mind high light levels in summer can be maintained only if a greenhouse has a correspondingly powerful cooling system.

Although I have grown orchids in a greenhouse for the last ten years or so, I previously grew under lights. In my experience, smaller-growing cattleyas thrive under fluorescent lights, but larger-growing species, including many large-flowered unifoliates, need high intensity discharge (HID) lights to grow to their full potential. I was able to successfully grow even the largest and most light-demanding (*Cattleya*) species under HID lights. Plants often benefit from going outside and getting a little fresh air and sunshine in summer; keeping plants outdoors under 50 percent shade cloth worked very well for me.

#### Watering, Potting, and Repotting

Watering and potting are integrally related. The most common reason to repot a cattleya is because the potting mix has begun to rot, becoming soggy and block-
plants as infrequently as possible; this applies or more years.

on plants whose roots have been undisturbed for three

decays very little over a year’s time. In this case, the

entire root ball can be removed and slipped into a larger

pot without significantly disturbing roots. In my expe-

ment schedule must be adjusted in response to changing

seasons, as well as week-by-week in the same season,

depending upon ambient sunlight and heat. The water-

ing schedule must be adjusted in response to changing

conditions. Be sure to run quite a bit of water through

the pot in order to leach out minerals and salts that can

affect the health of roots.

It is a mistake to overpot a cattleya under the prem-

ise that it will fill the pot in a few years like a geranium;

instead, it will decline and possibly die. I generally pot

my plants to allow for one or two years’ growth at most;

the roots will fairly quickly fill the pot and little or no

rotting of the medium occurs. Sometimes, when a plant

in a five or six inch pot is watered correctly, the medium

decays very little over a year’s time. In this case, the

entire root ball can be removed and slipped into a larger

pot without significantly disturbing roots. In my expe-

rience, the absolutely best blooms are often produced

on plants whose roots have been undisturbed for three

or more years.

One word of warning about my advice to disturb

plants as infrequently as possible; this applies only if

the medium has not begun to decay. Once decomposi-
tion sets in, the mix quickly becomes toxic to the plant,
and this can be even more detrimental than root dam-
age during repotting. So if you are unsure about the
condition of the medium, my recommendation is to re-
pot. Carefully observe the condition of the medium in

plants as you clean off the old mix, and you will devel-

op a better ability to judge from external appearances

whether the medium is decayed or not.

I grow most of my mature Cattleya species in plain

medium bark. For seedlings and small plants in pots

four inch or smaller, I make up a ‘fine bark mix’ consist-
ing of 5 parts fine fir bark, 1 part perlite, and 1 part fine

charcoal. For plants in 4 1/2” pots, I use a 50-50 mixture

of the above ‘fine bark mix’ and medium bark. These

media tend to dry out fairly quickly and thus decay

more slowly. I have begun to grow some of the most

finicky species that are unusually prone to rot (e.g., C.
dowiana and C. dowiana var. aurea) or unusually sensi-
tive to having their roots disturbed (e.g., C. schilleriana
and C. granulosa) in expanded clay pellets. These pellets

dry out more rapidly than bark, and because they are

inorganic, never rot.

I like to use clay pots in which I have drilled extra

holes in the bottom with a power drill. Drilling extra

holes is very important for two reasons: first, it allows

the pot to dry out more quickly, eliminating standing

water. Second, it becomes easier to run a lot of water

trough the pot to leach out excess salts and minerals.

I like clay pots because they ‘breathe’ and because they

are heavy, staying upright when a large plant leans

over the edge. I expect plastic pots would probably also

be adequate for someone who didn’t want to take the
time to drill extra holes in the bottom of all his or her

pots. Be cautious and gentle when repotting to mini-
mize damage. Since roots are more pliable and more

resistant to being broken or torn when they are wet, it

is a good idea to water a plant thoroughly before repot-
ting it. Cattleya roots often cling to clay pots; breaking

apart the pot on a concrete floor can help to detach the

roots with less damage. While this means you cannot

reuse the pot, in my opinion, clay pots should never be

reused in any event to prevent spread of viruses and

other diseases.

A few species, namely, C. aclandiae, C. walkeriana, and

C. nobilior, definitely grow much better when mounted

rather than potted. I mount these on cork and water

them every day (less frequently in mid-winter); they

grow like weeds, with no extra care required. When

potted, they grow poorly and (in the case of C. aclandi-

ae) sometimes die.

Over time, white mineral deposits can accumulate

on leaves of mounted plants that are watered every day

or frequently misted, especially in areas with high to-
tal dissolved solids (TDS) in the tap water. This white

crust of insoluble salts is unsightly and likely interferes

with photosynthesis. More importantly, these same

salts could be accumulating on the roots, which could

damage the sensitive growing tips and affect the plants’

health. Although our Chicago tap water comes from

Lake Michigan and is considered to be relatively low in

minerals, in years past I would still notice white depos-
its on my mounted plants. Then I installed an RO (re-

Orchid Digest, Oct., Nov., Dec. 2015
verse osmosis) water system, and this has completely solved the problem. I continue to water mounted plants with tap water once or twice a week to guard against mineral deficiency due to ultra-pure water. As a bonus, I can now use RO water to moist plants, too.

Temperature

According to most authors of orchid books, cattleyas are intermediate growers, requiring nights of 55–60°F (13-16°C) with daytime temperatures rising 10 to 15 degrees higher. I find that in my northern climate of Chicago, however, plants do better when I maintain a nighttime temperature of 65°F (18°C) in the winter, and daytime temperature of 75°F (24°C) using a thermostat and timer. While many plants in my collection enter a resting period for at least part of the winter, they seem healthier when resting at a slightly higher temperature. In summer, the challenge is cooling instead of heating. I use two large swamp coolers all summer. I intentionally oversized the capacity of my swamp coolers relative to the size of my greenhouse so that, even on a sunny humid day mid-summer, the greenhouse is a few degrees cooler than outside. A common cultural error of many hobbyist growers in small greenhouses is lack of sufficient cooling capacity, resulting in the high spikes in daytime temperatures that can be detrimental to plants. Growers sometimes try to compensate with excess shading; this can also be unhealthy for plants. So, to grow your plants in optimal light, you must have an extremely good cooling system.

Propagation from Backbulbs

Cattleyas, like other sympodial plants, can be propagated by removing backbulb divisions when plants are repotted. Sometimes a grower may find it very difficult to induce a back bulb to make a new growth and roots, particularly with some of the more finicky bifoliate species. This is often because roots on the backbulb are destroyed during repotting. The double shock of division and losing all of its roots is simply too much for the poor backbulb, and it expires. The solution is to sever the backbulbs while they are still growing in the pot, so a new growth has emerged from the backbulb by the time the mother plant is repotted. In some cases, I sever the backbulbs a few months before I expect to repot; the backbulb has a new growth ready to send out new roots when the time comes. In other cases, I sever the backbulbs a full year or more in advance, yielding a separate, fully established plant in the back of the pot by the time I divide it. I can generally produce good divisions from even truly pitiful-looking backbulb divisions using this technique.

About the Author

Bill Rogerson is an orchid hobbyist who lives in Chicago and specializes in growing and collecting Cattleya alliance species. He is an AOS Judge and has won over 100 AOS awards, mostly to Cattleya alliance species.

Always looking for the perfect Holiday gift?
Remember the gift that appears four times a year!

The Orchid Digest

Gift memberships received by December 1, 2015 will start with the year-end issue on Cattleyas with a card.

Gift memberships after December 1 will start with the first issue of 2016 and we will send a card announcing your gift.

See page 245 for ordering details.
